Multithreaded parallel Python through OpenMP support in Numba

Todd Anderson*, Timothy G. Mattson*

*Intel Corporation,

Abstract—A modern CPU delivers performance through parallelism. A program that exploits the performance available from a CPU must run in parallel on multiple cores. This is usually best done through multithreading. Threads belong to a process and share the memory associated with that process. The most popular approach for writing multithreaded code is to use directives to tell the compiler how to convert the code into multithreaded code. The most commonly used directive-based API for writing multithreaded code is OpenMP.

Python is not designed for parallel programming with threads. The GlobalInterpreterLock (GIL) prevents multiple threads from simultaneously accessing Python objects. This effectively prevents data races and makes Python naturally thread safe. Consequently, the GIL prevents parallel programming with multiple threads and therefore keeps Python from accessing the full performance from a CPU.

In this paper, we describe a solution to this problem. We implement OpenMP in Python so programmers can easily annotate their code and then let the Numba just-in-time (JIT) compiler generate multithreaded OpenMP code in LLVM, thereby bypassing the GIL. We describe this new multithreading system for Python and show that the performance in our early tests is on par with the analogous C code.

Index Terms—Python, OpenMP, Numba

I. INTRODUCTION

Python emphasizes productivity over performance. Given the growth of Python and the fact it is by some measures the most popular programming language in the world [3], this focus on productivity has turned out to be the right choice at the right time.

Performance from Python code, however, has suffered. The recent paper about software performance (“There’s plenty of room at the top...” [11]) used a simple triply nested loop for a matrix multiply routine and found that the Python code delivered results that, when rounded to the correct number of significant digits, were zero percent of the available peak performance from the chip.

The performance issues in Python come from a lack of focus on performance. They also emerge from a common attitude among Python programmers. Python is for developing new applications. If the performance of an application is not good enough, then the code is reimplemented in a low-level language such as C. Why bother with performance if people plan to rewrite code in C anyway?

In our line of research, we are trying to develop technologies that let programmers stay in Python. Some of our prior work in this area is ParallelAccelerator in Numba (i.e., the parallel=True option to the Numba JIT decorator) [1], [6], [10]. In this work, common patterns in code are exploited to expose concurrency in the code which is then executed in parallel. The parallelism is implicit in the patterns of code written by a programmer aware of these tools.

Implicit parallelism is powerful but there are too many cases where it can not find sufficient concurrency to support the levels of parallelism needed to fully occupy the cores on a modern CPU. A well-rounded Python tool chain needs to include explicit parallelism as well. With our focus on programming the cores in a CPU, this translates into utilizing multiple threads in parallel.

Multithreading for performance has been a foundational technology for writing applications in high performance computing for over four decades. Its use grew rapidly in 1997 with the introduction of OpenMP [8]. This API worked with C, C++ and Fortran compilers so a programmer could direct the compiler to generate multithreaded code through a sequence of directives. The power of OpenMP is that a programmer can add parallelism to a serial program incrementally, evolving a program step by step into a parallel program.

In this paper, we introduce PyOMP: a research prototype of a system where we add support for OpenMP directives in Python. PyOMP uses the Python with statement to expose the directives in OpenMP. These with statements are interpreted by our custom Numba JIT and combined with a backend that connects these constructs to analogous entry points in the generated LLVM code. This LLVM code is then compiled using the Intel LLVM system, which includes support for the full range of OpenMP constructs. For this early research prototype, we restrict ourselves to a subset of OpenMP known as the OpenMP Common Core [7]. We describe the subset of OpenMP supported from Python including the most common design patterns used by OpenMP programmers. We then discuss details of how we worked with Numba to implement this tool. Finally, we include some preliminary benchmark numbers and then close with a description of our future plans for PyOMP.

II. PYOMP: PYTHON AND OPENMP

OpenMP is a standard API that defines a set of compiler directives that can be used with C, C++ and Fortran to help applications programmers write multithreaded code. First released in 1997, it continues to be the most common way programmers in the high performance computing community write multithreaded code.

The standard has grown in size and complexity as it has evolved from version 1.0 to the current release (version 5.1). Important new features have been added over the years
including support for programming GPUs and detailed controls over how a computation is mapped onto many cores in a nonuniform address space. Most OpenMP programmers, however, restrict themselves to a subset of the OpenMP 3.0 specification released in 2008. This subset of the 21 most commonly used elements of OpenMP is called the “OpenMP Common Core” [7].

PyOMP is a research prototype of a system implementing OpenMP in Python. In PyOMP, we cover 90% of the common core. These are summarized in Table I. PyOMP is tied to the Numba JIT (just-in-time) compilation system. Any function using PyOMP must be JIT’ed with Numba. The contents of PyOMP are provided as a module included with Numba. The Numba compiler works with NumPy arrays which must be used for any arrays inside a PyOMP function.

The essence of OpenMP is the well-known fork-join parallelism foundational to most multithreaded programming models. A program begins as a serial thread. At some point, a compute intensive block of work is encountered. If this can be broken down into a set of tasks that can run at the same time AND unordered with respect to each other (in other words, they are concurrent), a team of threads is forked to do this work in parallel. When the threads are done, they join together and the original serial thread continues.

In essence, an OpenMP program is a sequence of serial and parallel executions. The API is expressed in terms of directives to the compiler which handles the tedious work of packaging code into functions for the threads, managing threads, and synchronizing the threads to maintain a consistent view of memory. The programming style is one of incremental parallelism so a program evolves in phases from a serial program into a parallel program.

Obviously, a detailed course on OpenMP is well beyond the scope of this paper. Instead, we present the three core design patterns used in OpenMP. These are SPMD (Single Program Multiple Data), Loop Level Parallelism, and Divide and Conquer with tasks. We will describe each of these patterns in turn and in doing so describe the key elements of PyOMP. We will apply these patterns to a single problem; the numerical view of memory. The programming style is one of incremental parallelism so a program evolves in phases from a serial program into a parallel program.

As with multithreaded programming environments in general, OpenMP is a shared memory API. The threads “belong” to a single process and they all share the heap associated with the process. Variables visible outside a parallel construct are by default shared inside the construct. Variables created inside a construct are by default private to the construct (i.e., there is a copy of the variable for each thread in the team). It is good form in OpenMP programming to make the status of variables explicit in an OpenMP construct which we do with the shared and private clauses in lines 14 and 15 in figure 1.

In an SPMD program, you need to find the rank (or thread number) and number of threads. We do this with OpenMP runtime functions in lines 16 and 18. The rank of a thread, threadID, is private since each thread needs its own value for its ID. All threads in a single team, however, see the same value for the number of threads (numThrds) so this is a shared variable. In multithreaded programming, it is a data race if multiple threads write to the same variable; even if the value being written is the same for each thread. So we must assure that only one thread sets the value for the number of threads. This is done with the single construct on line 17.

---

```python
from numba import njit
import numpy as np
from numba.openmp import openmp_context as openmp
from numba.openmp import omp_get_num_threads,
from numba.openmp import omp_get_thread_num
from numba import njit

@njit
def piFunc(NumSteps):
    step = 1.0/NumSteps
    partialSums = np.zeros(MaxTHREADS)
    startTime = omp_get_wtime()
    with openmp("single"):
        threadID = omp_get_thread_num()
        numThrds = omp_get_num_threads()
        print("number of threads =",numThrds)
        localSum = 0.0
        for i in range(threadID,NumSteps,numThrds):
            x = ((i+0.5)*step)
            localSum = localSum + 4.0/(1.0 + x*x)
            partialSums[threadID] = localSum

    pi = 0.0
    for i in range(threadID,NumSteps,numThrds):
        pi += partialSums[i]
    print(pi)
    return pi

start = omp_get_wtime()
pi = piFunc(100000000)
print("time including JIT time",omp_get_wtime()-start)
```

---

Fig. 1. A program using the SPMD pattern to numerically approximate a definite integral that should equal π.

---

A. The SPMD Pattern

A classic use of the SPMD pattern is shown in figure 1. In an SPMD pattern, you create a team of threads and then, using the rank of a thread (a number ranging from zero to the number of threads minus one) and the number of threads, explicitly control how work is divided between the threads. Threads are created with the parallel construct expressed in PyOMP using the with context statement. We see this in line 14-15. The identifier openmp indicates this is an element of PyOMP and parallel indicates that the compiler should fork a team of threads. These threads come into “existence” at that point in the program and they each redundantly execute the work in the code associated with the with statement. This code is called a structured block in OpenMP and is outlined into a function that will be passed to each thread in the team. OpenMP requires that a structured block has one point of entry at the top and one point of exit at the bottom (the only exception being a statement that shuts down the entire program).

As with multithreaded programming environments in general, OpenMP is a shared memory API. The threads “belong” to a single process and they all share the heap associated with the process. Variables visible outside a parallel construct are by default shared inside the construct. Variables created inside a construct are by default private to the construct (i.e., there is a copy of the variable for each thread in the team). It is good form in OpenMP programming to make the status of variables explicit in an OpenMP construct which we do with the shared and private clauses in lines 14 and 15 in figure 1.

In an SPMD program, you need to find the rank (or thread number) and number of threads. We do this with OpenMP runtime functions in lines 16 and 18. The rank of a thread, threadID, is private since each thread needs its own value for its ID. All threads in a single team, however, see the same value for the number of threads (numThrds) so this is a shared variable. In multithreaded programming, it is a data race if multiple threads write to the same variable; even if the value being written is the same for each thread. So we must assure that only one thread sets the value for the number of threads. This is done with the single construct on line 17.
The extent of the parallel algorithm is the for-loop starting at line 22. Each thread starts with a loop iteration \( i \) equal to its rank, which is incremented by the number of threads. The result is loop iterations dealt out as if from a deck of cards. This commonly used technique is called a “cyclic distribution of loop iterations”. This loop is summing values of the integrand which we accumulate into a private variable for each thread. Since we need to later combine these local sums to get the final answer (on line 27), we store the local sum into a shared array \( \text{partialSums} \) on line 25.

The parallel region ends at line 25 at which point the team of threads join back together and the single original thread continues. We time the block of code with calls to the OpenMP runtime function \( \text{omp_get_wtime()} \) (lines 13 and 28) which returns the elapsed time since a fixed point in the past. Hence, differences in time values returned from \( \text{omp_get_wtime()} \) provides the elapsed time for execution of a block of code. We show runtimes for this SPMD program in table I and compare to the same algorithm implemented in C. The runtimes are comparable. This supports our assertion that once the path for execution passes from the Python interpreter to machine code via Numba and LLVM, performance should match that from lower-level programming languages passing through the same LLVM/runtime infrastructure.

### B. Loop Level Parallelism

The Loop Level Parallelism pattern is where most people start with OpenMP. This is shown in figure 2. The code is almost identical to the serial version of the program. Other than the import and timing statements, parallelism is introduced through a single \texttt{with} statement to express the \texttt{parallel for} construct. This construct creates a team of threads and then distributes the iterations of the loop among the threads. To accumulate the summation across loop iterations, we include the \texttt{reduction} clause. This clause defines reduction with the \texttt{+} operator over the variable \texttt{sum}. A copy of this variable is created for each thread in the team. It is initialized to the identity for the operator (which in this case is zero). At the end of the loop, all the threads wait for the other threads (a synchronization operation called a \texttt{barrier}). Before exiting the barrier, the local copies of sum are combined into a single value, that value is combined with the value of sum from before the parallel loop construct, and the threads join so only the single, original thread continues.

This program uses the default number of threads established outside the code of the program. This is set using an environment variable, \texttt{OMP_NUM_THREADS}; hence, we run our program \texttt{pi_loop} with the command line:

\begin{verbatim}
OMP_NUM_THREADS=16 python pi_loop.py
\end{verbatim}

The results for this pattern are shown as the second column in table I. Once again, the performance is similar to that achieved with the C version of the program.

### C. Tasks and Divide and Conquer

Our final pattern is more complex than the other two. This important pattern is heavily used by more advanced parallel programmers. A wide range of problems including optimization problems, spectral methods, and cache oblivious algorithms use the divide and conquer pattern. The general idea is to define three basic phases of the algorithm: split, compute, and merge. The \texttt{split phase} recursively divides a problem into smaller subproblems. After enough splits, the subproblems are small enough to directly compute in the \texttt{compute phase}. The final phase merges subproblems together to produce the final answer.

A divide and conquer solution to our \texttt{pi} problem is shown in figure 3. We start by creating a team of threads on line 37. We use the \texttt{single} construct to select one thread to start the algorithm with a call to our recursive function \texttt{piComp()}. With the \texttt{single} construct, one thread does the computation within the construct while the other threads wait at the end of the \texttt{single} construct (a so-called implied barrier). While those threads wait at the barrier, they are available for other computation on behalf of the program.

Inside the \texttt{piComp()} function, we test if the problem size is small enough for direct computation (is it smaller than a

print(" time with JIT = ",ompomp_get_wtime()-startWithJit)

Fig. 3. A program using the divide-and-conquer pattern with tasks to numerically approximate a definite integral that should equal π.

minimum block size) on line 13. If it is, we just compute the numerical integration for that block of loop iterations (lines 14 to 17) and return the partial sum (line 30). If an instance of the function, piComp(), has a block of iterations greater than MIN_BLK, we enter the split phase of the algorithm. The split occurs in lines 19 to 25 using the task construct. This construct takes the code associated with the construct (in this case, a single line) and outlines it with its data environment to define a task. This task is placed in a queue for other threads in the team to execute. In this case, that would be the threads waiting at the barrier defined with the single construct on line 38.

As tasks complete, we enter the merge phase of the algorithm. This occurs at lines 27 and 28. The task that launches a pair of tasks must wait until its “child tasks” complete. Once they do, it takes the results (the shared variables sum1 and sum2), combines them, and returns the result. The results are summarized in table I. Even though the code is more complex than for the other two patterns, the runtimes for this simple problem are comparable to the other patterns for both Python and C.

III. NUMBA AND THE IMPLEMENTATION OF PYOMP

Numba is a Just In Time (JIT) compiler that translates Python functions into native code optimized for a particular target. The Numba JIT compiles PyOMP to native code in 4 basic phases.

1) Untyped phase: Numba converts Python bytecode into its own intermediate representation (IR), including “with” contexts that are OpenMP-represented in the IR as “with” node types, and performs various optimizations on the IR. Later, Numba removes these “with” nodes by translating them to other node types in the IR. For our PyOmp implementation, we added a new OpenMP node type into the IR, and we convert OpenMP with contexts into these new OpenMP IR nodes. See Section III-A for a detailed description.

2) Type inference phase: Numba performs type inference on the IR starting from the known argument types to the function and then performs additional optimizations. No changes were made to the Numba typed compilation phase to support OpenMP.

3) IR conversion phase: Numba converts its own IR into LLVM IR.

4) Compilation phase: Numba uses LLVM to compile the LLVM IR into machine code and dynamically loads the result into the running application.

For PyOmp, we replaced the mainline LLVM normally used by Numba with the custom LLVM used within the Intel compiler, icx. This custom icx LLVM supports the bulk of OpenMP through two special function calls to demarcate the beginning and end of OpenMP regions (we will refer to these as OpenMP_start and OpenMP_end respectively) and LLVM tags on those function calls are used to apply the equivalent of OpenMP directives/declarations to those regions. Our PyOMP prototype passes the equivalent of the “-fopenmp” icx compiler option to the icx LLVM which causes it to convert the demarcated OpenMP regions into OpenMP runtime function calls. The Intel OpenMP runtime is thus also needed and loaded into the process by the PyOMP prototype OpenMP system. In PyOMP during the third phase, we convert the Numba OpenMP IR nodes to these two special function calls along with the corresponding LLVM tags. Additional details are described in Section III-B.

OpenMP includes a number of runtime functions to interact with the system as a program runs. This is used to manage the number of threads, discover thread IDs, measure elapsed time, and other operations that can only occur as a program executes. For these functions, our prototype using CFFI [2] to make those functions from the OpenMP runtime accessible from Python. The importing of some of these functions such as omp_get_num_threads, omp_get_thread_num, omp_get_wtime, and omp_set_num_threads can be seen,
for example, in the initial from numba.openmp import... lines at the beginning of the code example in figure 1.

A. Converting PyOMP with clauses to Numba IR

When removing OpenMP with contexts and replacing them with Numba IR nodes, Numba provides basic block information to demarcate the region that the with context covers. PyOMP places one OpenMP IR node at the beginning of this region and one at the end with a reference from the end node back to the start node to associate the two. To determine what to store in the OpenMP IR node, PyOMP first parses the string passed to the OpenMP with context to create a parse tree. Then, we perform a postorder traversal of the parse tree, accumulating the information as we go up the tree until we reach a node that has a direct OpenMP LLVM tag equivalent. At this point, we convert the information from the sub-tree into tag form and then subsequently pass that tag up the parse tree. These tags are accumulated as lists of tags up the parse tree until the traversal reaches a top-level OpenMP construct or directive, which have their own tags. Some of these directives are simple and require no additional processing whereas others, particularly those that support data clauses, require additional clauses to be added to the Numba OpenMP node that are not necessarily explicitly present in the programmer’s OpenMP string. For example, all variables used within the parallel, for and parallel for directives must be present as an LLVM tag even if they are not explicitly mentioned in the programmer’s OpenMP statement. Therefore, for these directives our PyOmp prototype performs a use-def analysis of the variables used within the OpenMP region to determine if they are also used before or after the OpenMP region. If they are used exclusively within the OpenMP region then their default data clause is private. In all other cases, the default data clause is shared but of course these defaults can be overridden by explicit data clauses in the programmer OpenMP string. For looping constructs, icx LLVM only supports loops in a certain canonical form that differs from the standard Numba IR loop form. For this purpose, our prototype transforms the Numba IR loop structure to match the icx LLVM loop structure.

B. Converting PyOMP Numba IR to LLVM

When a Numba OpenMP IR node is encountered in the process of converting Numba IR to LLVM IR, that node is converted to an LLVM OpenMP _start (or OpenMP_end) call. Inside the Numba OpenMP node is a list of the clauses that apply to this OpenMP region and we perform a 1-to-1 conversion of that list of clauses into a list of LLVM tags on the LLVM OpenMP_start call. We emit code that captures the result of the LLVM OpenMP_start call and we pass that result as a parameter to the OpenMP_end, which allows LLVM to match the beginning and end of OpenMP regions.

In the process of converting Numba OpenMP IR nodes and the intervening OpenMP regions to LLVM, we disable certain Numba functionality. Numba unifies the handling of exceptions and return values by adding an additional hidden parameter to functions it compiles that indicates whether the function has returned normally with a given return value or is propagating an exception. After a call site, Numba inserts code into a caller to check if the callee function is propagating an exception by inspecting the callee’s hidden parameter. If there is an exception, the caller places that exception in its own hidden parameter and returns. However, this approach of using returns for exceptions breaks the icx LLVM requirement that OpenMP regions be single-entry and single-exit. Likewise, exceptions generated from within the caller, such as divide-by-zero, also fill in the exception information in the hidden parameter and immediately return, again breaking the single-entry/exit requirement. It is not currently possible to explicitly catch such exceptions in

TABLE II

SUMMARY OF THE ELEMENTS OF OPENMP INCLUDED IN PYOMP. THIS INCLUDES CONSTRUCTS (USING THE PYTHON WITH STATEMENT), CLAUSES THAT MODIFY CONSTRUCTS, FUNCTIONS FROM THE OPENMP RUNTIME LIBRARY, AND A SINGLE ENVIRONMENT VARIABLE. THESE ELEMENTS INCLUDE 19 OF THE ELEMENTS IN THE OPENMP COMMON CORE (MISSING ONLY NOWAIT AND THE DYNAMIC SCHEDULE).
PyOMP Numba regions because the Numba exception catching mechanism also generates control flow that violates single-exit. As such, in our PyOMP prototype, inside OpenMP regions, exception handling is currently elided.

The Numba process of converting Numba IR to LLVM IR introduces many temporary variables into the LLVM IR that are not present in the Numba IR. Thus, these variables are not visible in the untyped phase in which the data clauses for all variables accessed in OpenMP regions are determined. Such temporaries used solely within an OpenMP region should be classified as private in the tags associated with the surrounding OpenMP region’s OpenMP_start demarcation function call. In PyOMP, we implemented a callback in the Numba function that creates these LLVM temporary variables such that we can learn of the existence of these new variables and to add them as private to the previously emitted tags of the surrounding OpenMP region.

Finally, certain OpenMP directives such as single and critical, require the use of memory fences with acquire, release, or acquire/release memory orders. Our prototype knows which directives require which kind of fences and we store that information in the Numba OpenMP IR node as those are created during the untyped phase. During conversion of those OpenMP IR nodes to LLVM, if the node require memory fences then we insert the equivalent LLVM fence instructions into the LLVM IR.

IV. RESULTS

The key result of this paper is that PyOMP works. As we saw in Table I, we achieved reasonable speedups for the three key patterns that dominate OpenMP programming where by the word “reasonable” we mean “achieving performance similar to that from C”. The π programs used in section II, however, are “toy programs”. They are useful pedagogically but are far removed from actual applications.

One step above a “toy program” is dense matrix multiplication. While this is a simple program lacking in the inevitable complexities faced by real applications, dense matrix multiplication uses a familiar loop-nest and data access patterns found in real applications. It has the further advantage that dense matrix multiplication over double precision values (DGEMM) is compiler-friendly. If a compilation tool-chain is going to work well, DGEMM is where this would be most inevitable complexities faced by real applications, dense matrix multiplication over double precision values (DGEMM) is compiler-friendly. If a compilation tool-chain is going to work well, DGEMM is where this would be most.

Our DGEMM code comes from the Parallel Research Kernels (PRK) [9] version 2.17. All code is available from the PRK repository [3]. The PyOMP code is summarized in figure 4. The numba JIT was done with the fastmath option. This resulted in a 20% performance improvement. Numba and therefore PyOMP requires that any arrays use NumPy. They are allocated and initialized on lines 21 to 25. The ikj loop order is used since it leads to a more cache-friendly memory access pattern. The elapsed time is found (dgemmTime) and reported as GF/s (billions of floating point operations per second or GFLOPS).

We compare performance from PyOMP to the analogous program written with C/OpenMP, NumPy arrays with the ikj loop-nest, and a call to the matrix multiplication function included with NumPy. Code fragments for these cases are shown in figure 5. The C DGEMM program was compiled with the Intel® icc compiler version 19.1.3.304. The compiler command line was:

```
icc -std=c11 -pthread -O3 -xHOST -qopenmp
```

We ran all computations on an an Intel® Xeon® E5-2699 v3 CPU with 18 cores running at 2.30 GHz. For the multithreaded programs with OpenMP we forced the threads to map onto specific cores with one thread per core using the following pair of environment variables:

```
export OMP_PLACES="{0},{1},{2},{3},{4}"
export OMP_PROC_BIND=close
```

Fig. 4. A PyOMP program to multiply two matrices.
number of threads used in the computation. When combined
with the processor binding term (close) this connected the
OpenMP thread ID with the core ID (e.g., OpenMP thread ID
0 ran on core 0). This way, we knew that the C and Python
OpenMP programs used precisely the same cores and had
the same relationship to the memory controllers on the chip.

We choose a matrix order large enough to create sufficient
work to overcome memory movement and thread overhead.
These matrices were too large for the computation to complete
on our system for matrices represented through Python lists.
Using numpy arrays with triply nested loops in $i, k, j$ order,
the computation ran at 0.00199 GFLOPS. For our scalability
studies, all runs were repeated 250 times. Averages and standard
deviations in GFLOPS are reported. Results are shown in
table [11] For the PyOMP results, we do not include the JIT
times. These were only done once per run (i.e. not once per
iteration) and took on the order of two seconds.

The PyOMP and the C are comparable with the C results
consistently around 2.8 percent faster than the results from
PyOMP. We performed a Welch’s T-test for the two sets of
data in Table III. The test showed that while the difference
between the PyOMP and C cases are small, they are statistically
significant to the 99% confidence level.

If we use NumPy and call the matrix multiplication function
provided with NumPy (line 22 in figure [5] the order 1000
DGEMM ran at 11.29 ± 0.58 GFLOPS with one thread (using
the matmul() function from numpy). This high performance
serves to emphasize that while DGEMM is a useful benchmark
to compare different approaches to writing code, if you ever
need to multiply matrices in a real application, you should
use code in a library produced by performance optimization experts.

V. DISCUSSION

In the paper “There’s plenty of room at the top...” [11], much
was made of the low performance available from code written
in Python. They motivated their discussion using DGEMM.
The implication was that when you care about performance,
rewrite your code in C. We understand that sentiment and
often use that strategy ourselves. Our goal, however, is to meet
programmers “on their turf” and let them “stay with python”.

One of the key challenges to the “stay with python” goal is
multithreading. Because of the GIL, if you want multithreaded
code to execute in parallel, you can’t use Python. In this paper,
we have addressed this issue by using Numba to map onto
LLVM and the OpenMP hooks contained therein. This resulted in
our Python OpenMP system called PyOMP.

The performance from PyOMP was within a few percent of
performance from OpenMP code written in C. Performance
differences were statistically significant, but we believe not
large enough to justify rewriting code in C. This holds for
a subset of OpenMP supported in PyOMP (known as the
“Common Core” [7]) and for the three fundamental design
patterns used by OpenMP programmers.

PyOMP is a research prototype system. It is a proof-of-
concept system we created to validate that Numba together
with LLVM could enable Multithreaded programming in Python
through OpenMP. A great deal of work is needed to move from a
research prototype to a production-ready tool for application
programmers.

- We need to develop a formal test suite. We currently have
  a test suite that covers each PyOMP OpenMP construct in
  isolation. In those tests, we use a very limited subset (e.g.,
  ints, floats, NumPy arrays, prints, assignments) of the
  Python features supported by Numba [4]. We need a test
  suite that covers the combinations of OpenMP constructs
  encountered in real OpenMP applications with the full set
  of data types and Python features supported by Numba.
  In this process, we will note Numba features incompatible
  with OpenMP (such as ParallelAccelerator [6]); fixing the
  cases we can fix and documenting those we can’t.

- We need to work out the details for how we will distribute
  this code. We used the Intel production LLVM-based
  compiler which ties PyOMP to Intel proprietary tools. We
  need to investigate whether the OpenMP support in the

Fig. 5. We compare our PyOMP program to three other cases: C with OpenMP,
serial code using the NumPy array, and the matmul() built in function for
matrix multiplication. All programs use the same matrices, tests for correctness,
and performance metrics (shown in figure [4]), hence that code is not reproduced
here.

```
\--- The computation from the C PRK DGEMM
#pragma omp parallel for
for (ig=0; ig<order; ig++)
for (kg=0; kg<order; kg++)
C_arr(ig,jg) += A_arr(ig,kg)*B_arr(kg,jg);
\---
\--- The python program for DGEMM using NumPy arrays
# 0.00199 GFLOPS for order 1000 matrices (one thread)
for i in range(order):
  for k in range(order):
    for j in range(order):
      C[i][j] += A[i][k] * B[k][j]
\---
\--- The python program for DGEMM using the matmul
# 9.02 GFLOPS order 1000 matrix
C += numpy.matmul(A,B)
```

Intel open source release of LLVM is sufficient to support PyOMP.

- Currently, exception handling in PyOMP is disabled due to the interaction of how Numba manages exceptions with how LLVM manages execution of structured blocks in OpenMP. We are investigating ways to address this problem, but don’t have a solution at this time.

- We currently disable the Numba static single assignment mode (SSA). In this mode, Numba creates variants of variables. Those names are difficult to track relative to the data environment of OpenMP. We believe we can account for these variants in PyOMP, but we have not done so yet.

In additions to refinement to PyOMP itself, we need to conduct a formal benchmarking effort with benchmarks that exercise the system in the way real applications would. In this effort we also need to compare to the performance of other systems for parallel programming for a CPU with Python. In particular, we want to understand the performance tradeoffs between PyOMP, Dask, MPI4Py, and implicit parallelism through Numba’s ParallelAccelerator.
